

Cell text = $\log_2(\text{habitat rate} / \text{dataset-wide phaC-positive rate})$, Haldane-Anscombe corrected. Color is normalized per column (not globally) since phaAB/phaJ have high baseline prevalence (85.6%/65.2%) and so are mathematically capped near ± 0.6 , while phaG/Both J&G (baseline 5.5%/4.4%) can swing several $\log_2$ units -- a shared scale would wash out the first two columns.
 15 habitats with ≥ 20 phaC-positive genomes shown. * $p < 0.05$, ** $p < 0.001$ (phylum-controlled CMH test). Rows ordered by phaAB enrichment, most- to least-enriched.

mcl-PHA precursor route enrichment by habitat
